

New Treatment of Alzheimer's Disease

Hanlin You

School of Fujian Medical University, Fuzhou, China

18403245@masu.edu.cn

Abstract. Alzheimer's disease is a major degenerative disease characterized by impaired memory, aphasia, apraxia and the changes of personality and behavior. As the population ages, the incidence of AD is increasing. According to an analysis of 10000 people with up to 30 years of follow-up data, elderly over 55 years old, the risk of dementia increased nearly four- fold if they have three or more chronic diseases at the age of 55. The pathogenesis of AD has not been fully studied, a lot of mechanisms such as neuroinflammation, mitochondrial dysfunction, abnormal metabolic are related to the pathology of AD. The abnormal deposition of A β and hyperphosphorylation of Tau protein are identified mechanism of AD. Finding new drugs for AD has always been a research hotpot, preclinical work of new anti-AD drugs is being carried out on a large scale in the world. However, in all types of new developing drugs for AD, the failure rate is about 99%. The drugs approved to treat AD such as acetylcholinesterase inhibitors and glutamate receptor antagonists, only slow symptoms other than change the progression of this disease. Deep researches are required to study the pathogenesis of AD, developing drugs that can reverse the progression is the key to the treatment for AD. This review introduces new developing therapy and potential targets of future research into treatments of AD.

Keywords: Alzheimer's disease, pathogenesis, new developing drugs

1. Introduction

Alzheimer's disease is a severe degenerative disease affecting majority of people over the age of 65. AD, the most prevalent kind of dementia, is characterized by cognitive impairment, changes of personality, and a decline of quality of life. As the world's population ages, AD will certainly impose major social and economic burdens on the world.

Growing evidence has shown that the pathologies of AD are complex. Some features of AD in gray matter include excessive deposition of β -amyloid, neurofibrillary formatting, degeneration of Tau protein and neuroinflammation. Metabolic or mitochondria function are also abnormal, as shown in Figure 1. Furthermore, demyelination in white matter occurs in the early stage of AD. AD has a high heritability, there are some related gene like APP, PSEN1, APOE, which was verified to have a clear relationship with AD. Environment is also a factor of AD such as environmental pollution, medical development. Currently, the diagnosis of AD relies on some scales designed to assess the cognitive ability of patients. In terms of pathological evaluation of AD, the most commonly used medical procedures are brain imaging and lumbar puncture to identify the lesions in brain caused by AD. Compared to Imaging technology and lumbar puncture, the plasma-based detection is easy to use and less costly, and it is likely to become an alternative method for AD detection. In addition to blood markers like A β 1-42, A β 1-40, or phosphorylated Tau protein 181, some new cerebrospinal fluid

biomarkers such as Neurogranin, SNAP25 have been added [1].

Pharmacotherapy is still the dominant treatment of AD. Currently approved drugs for AD in clinical use like cholinesterase inhibitors (ChEIs) and NMDA receptors antagonist(memantine) have beneficial effects on symptoms but do not effectively slow the progression of the disease. ChEIs are currently primary drugs for the treatment of mild to moderate AD, mainly including donepezil, rivastigmine, galantamine, and huperzine A. In recent years, a randomized double-blind trial in China found that donepezil was effective in the treatment of severe AD [2]. However, these drugs are suitable for the patients in early stage. After long-term use, some patients have great side effects, and the drug's effective time is shortened. Although much efforts have been made to develop novel drugs targeting at neuroinflammation, mitochondrial function or metabolism other than β -amyloid and Tau protein, current clinical tests haven't achieved promising results. Non-drug therapy can be adjunct to drug therapy. Besides, non-drug therapy is less invasive and harmful to patients compared to drug therapy. This paper introduces some new developing drugs for AD, targeting at different mechanisms.

Figure 1. Different hypothesis of Alzheimer's disease.

2. Non-drug therapy

2.1. Physical therapy

2.1.1. Multi-sensory gamma stimulation. Giving 40HZ light-sound stimulation to Hippocampus and prefrontal cortex has a profound impact on reducing the deposition of $A\beta$ plaque and Tau protein. Long-term exposure to 40HZ light improves not only the function of synapsis and microglia acting through phagocytosis, but also alleviates immunological inflammation [3]. In mild and moderate patients, this innovative therapy has achieved II-stage clinical findings. The results showed that after 6-months treatment, the sleep and cognition of AD patients improved noticeably, and the loss of brain volume decreased by 65 percent [4].

2.1.2. A deep brain stimulation. A deep brain stimulation (DBS) has been shown to help with Parkinson's disease, memory and other conditions. DBS may work in memory circuits by reducing synaptic loss, boosting neurogenesis and improving glucose metabolism. DBS aims improve memory by coordinating activity across many brain regions. Furthermore, it has potential to lower $A\beta$ plaque load DBS is a revolutionary treatment for AD that targets at entorhinal cortex and hippocampus directly [5].

2.2. Hyperbaric oxygen therapy

Patients who receive hyperbaric oxygen therapy (HBOT) breathe 100% oxygen in a controlled setting. Eliminating cerebral edema to reduce intracranial pressure and reducing oxygen deficiency to the brain are two probable methods of HBOT. Patients with AD improved in numerous areas after receiving

HBOT treatment, including memory, blood flow in the brain, attention and their information processing ability [6]. This therapy is currently in preclinical stage.

2.3. *Mesenchymal stem cell therapy*

Lomecel-B, a novel mesenchymal stem cell treatment, promotes tissue healing while also regulating the immune system. This approach reduces brain inflammation and enhances the function of blood vessels. Anti-inflammatory molecules such as IL-4, IL-6, IL-10 were significantly increased in patients with different doses of Lpmececel-B in the phase I of clinical trial as compared to placebo. Furthermore, the volume of left hippocampus was larger than that in both low-dose group and placebo. Patients given low-dose Lomecel-B saw an obvious improvement in their quality of life after 26-weeks of treatment [7].

2.4. *Plasma exchange with albumin replacement*

Plasma exchange with albumin replacement (PE) is a novel treatment for AD that has passed phase IIb/III trial. Plasma from AD patients contains A β as well as highly oxidized albumin, which impairs the albumin's antioxidant activity. This therapy can improve the antioxidant activity of plasma. Some symptoms in patients with mild-AD such as processing capacity and speaking fluency got improved after PE treatment. The short-term memory in moderate-AD patients also got enhanced. Patients who had PE treatment had a higher quality of life in general [8].

2.5. *Gene therapy*

Microglia-specific microRNAs (miRNAs) contribute a lot in neuropathologies and therapy in AD. For example, MiRNA-200c, miR-206-3P, miR-30a-5p showed anti-AD properties [9,10]. However, because miRNAs are shared by hundreds of genes, some miRNAs gene or protein clusters may be better markers of AD. NHE6, a Na⁺-H⁺ exchanger, regulates endosome PH by exchanging acidic protons for sodium ions. When NHE6 gene was turned off in the mouse model, their deposition of A β was reduced. The PH-regulating protein can be produced with this therapy. As a result, intracellular environment becomes more acidic, and the accumulation of A β is prevented [11]. Apolipoprotein E4 (ApoE4) gene is a known risk factor for AD, which might be substituted with ApoE2 utilizing an adeno-associated virus (AAV) based gene therapy. ApoE2 plays a protective role in AD. ApoE4 homozygous persons are approximately 15 times more likely to develop AD than ApoE4 non-carriers [12]. The LEXEO firm developed an AAV-based gene therapy in which ApoE2 is delivered to central nervous system to replace ApoE4. This treatment lowered the level of Tau and phospho-Tau in patients' brains.

3. **New developing drug-therapy**

3.1. *Drugs regulating metabolism*

3.1.1. *GLP-1*. AD called "Type 3 diabetes", is thought to be associated with insulin resistance that is a major problem in type2 diabetes. Patients with type2 diabetes are more prone to develop AD. The incidence of dementia is reduced when they are treated with Recombinant Human Glucagon Like Peptide-1 (GLP-1) [13]. Many studies have shown that GLP-1 has neuroprotective effects in the transgenic mice model of AD. It can improve cognitive performance and oxidative stress by activating the PI3K/Akt pathway, which increases aerobic glycolysis and reduces oxidative phosphorylation [14]. Oral semaglutide which promotes insulin secretion and inhibits glucagon secretion has been approved in US, Europe and Japan. Its main function is to control blood glucose in patients with Type2 diabetes. Semaglutide is now undergoing clinical trials to determine its effectiveness on AD.

3.1.2. *Targeting at mitochondrial function*. Mitophagy plays a key role in inhibiting the accumulation of A β . UMI-77, a small molecule inhibitor of Myeloid cell leukemia-1(Mcl-1), was discovered to safely and effectively induce mitophagy by using a sensitive quantitative detection from the FDA-approved

drug candidate. It doesn't damage mitochondrial. It has the ability to degrade damaged mitochondria selectively. Mitophagy was successfully induced in mouse brain tissue after intraperitoneal injection of UMI-77 at a dose of 10mg/kg. The mechanism is that UMI-77 releases MCL-1 from Bax/Bak, which then combines with LC3A located on outer membrane of autophagy lysosome. The memory and cognitive abilities of AD mice improved after the treatment with UMI-77, and the area of A β plaques in the hippocampus was also reduced [15].

3.1.3. Targeting at gut microbial. Gut-Brain Axis is a potential pathway in AD. Sodium oligomannate (GV-971) is a marine algae-derived oral oligosaccharide first approved in November 2019 in China. It can help people with mild to moderate AD enhance their cognitive performance by regulating gut-microbiota-brain axis. It also inhibits aberrant increase of specific metabolites of intestinal flora. Furthermore, GV-971 has the ability to infiltrate the brain, and inhibits A β formation directly. GV-971 has been shown to be safe and tolerable in phase I and II studies. Objects with GV-971 900mg had improved cerebral glucose metabolism and dramatically enhanced memory in phase II [16]. A 36-week study of GV-971 in phase III clinical trial demonstrated obvious improvement of cognition in AD subjects (relative to placebo, $p < 0.0001$) [17].

3.2. Targeting at A β

β -amyloid is a substance that can be cleared away from the brain in a healthy state. However, during the aging process of human brain, because of neuron's intaking disorder, these amyloid plaques become insoluble amyloid fibrils. Deposition of insoluble amyloid fibrils leads to the death of nervous cells, resulting in impaired cognition. Because the cells in the brain generally don't regenerate, excessive damage can be irreversible.

Donanemab is an antibody that targets A β epitope of N-terminal pyroglutamate, which reached a breakthrough in phase II of clinical trial. Using an integrated Alzheimer's disease scale (iADRS), researchers discovered that individuals who got donanemab medication for 76 weeks had a 32% lower in iADRS score than that in placebo group ($p < 0.05$). It meant that patients who received donanemab had a lower rate of cognitive loss. Meanwhile, PET imaging technology revealed a rapid clearance of A β in patients' brains after donanemab treatment, but there was no improvement of Tau position. Around 68% of patients had a PET-negative result after 18 months of treatment [18,19].

Lecanemab (BAN2401) is a humanized IgG1 monoclonal antibody that targets soluble aggregated A β (including oligomers and fibrils) and insoluble fibrils. It has completed phase II of clinical trial. The highest dose about 10mg/kg of lecanemab was able to decrease A β in the patients' brains. It also revealed a drop in A β levels that was time-dependent [20].

Aducanumab is a fully humanized IgG1 monoclonal antibody, it binds selectively with A β in patients' brains, then it activates immune system to eliminate the deposition of A β . However, a study found that patients given a high dose of aducanumab experienced some negative effects. More studies are required to assess its effectiveness and safety [21].

Varoglutamstat is an oral small-molecule drug that inhibits pyroglutamate-A-beta (pGlu A β 42), which is related to the formation of A β plaque. Tau pathology, neuroinflammation and synaptic function are all negatively affected by pGluA β 42. Varoglutamstat is currently in phase II of clinical trials [22]. PBD-C06 is a humanized, deimmunized IgG1 antibody designed to bind to pGluA β 42 in the brain and remove it. A research using mouse model showed that using a single treatment (Varoglutamstat or PBD-C06) reduced pGluA β 42 in brain of mice by 16-41%. Moreover, combining these two medications reduced pGluA β 42 by 45-65%, which was a considerable improvement [23].

3.3. Targeting at Tau protein

Protein Degradation Targeting Consortium (PROTAC) and Active Peptide Vaccine AADvac1 are two new therapies that target Tau protein and eliminate Tau aggregation.

PROTAC makes two kinds of protein close to each other, allowing for targeted protein degradation. It is composed of a ligand for binding target protein, a ligand for recruiting E3 ligase and a linker. PROTAC

efficiently eliminated Tau aggregation in 3xTg-AD mouse model, improving cognition and synaptic functions [24].

AADvac1 is a Tau protein-targeted active peptide vaccination. A phase II of clinical trial for this vaccine has been completed. It demonstrated that AADvac1 is relatively safe and tolerable. AADvac1 significantly reduced the accumulation of neurofilament light chain protein (NFL) by 58%, a key marker of neurodegenerative diseases. Furthermore, tau and phosphor-tau are reduced in cerebrospinal fluid (CSF) [25]. However, there was no statistically significant benefit from this vaccine in terms of cognition.

4. Others

4.1. Levetiracetam

About 10% to 20% of patients with AD have seizures, whereas an estimated 22-54% have asymptomatic epileptic activity. According to a clinical trial, low-dose levetiracetam improved spatial memory and executive function tasks in patients with AD. Levetiracetam (100 and 150 mg/kg) significantly attenuated learning impairments in rat model of AD [26]. However, there is no evidence that levetiracetam can slow the progression of AD, so more studies are needed [27].

4.2. Axitinib

Axitinib, an anticancer drug, is a small-molecule tyrosine kinase inhibitor that targets the vascular endothelial growth factor receptor. In the Tg2576 transgenic mouse, a typical pre-clinical model of AD, axitinib targets the pro-angiogenic pathway in AD, restoring the integrity of blood-brain barrier and reducing A β deposition [28]. As a result, rather than directly targeting A β , anticancer drugs that affect cerebral angiogenesis may be a viable therapy for AD.

4.3. Phosphodiesterase-5 inhibitors

Sildenafil is a selective phosphodiesterase-5 inhibitor, it has been approved to treat erectile dysfunction (ED) in males. Sildenafil may treat AD through a variety of potential mechanisms. The NO/cGMP pathway in the hippocampus, which is related closely to long-term potentiation (LTP) is disrupted in AD. The enzyme phosphodiesterase-5 which breaks down cGMP is elevated. PDE5 is inhibited by Sildenafil which raises cGMP levels [29]. In vitro experiments showed that Sildenafil increased neurite outgrowth and reduce aberrant phosphorylation of Tau protein. These findings show Sildenafil plays a potential role in treating AD.

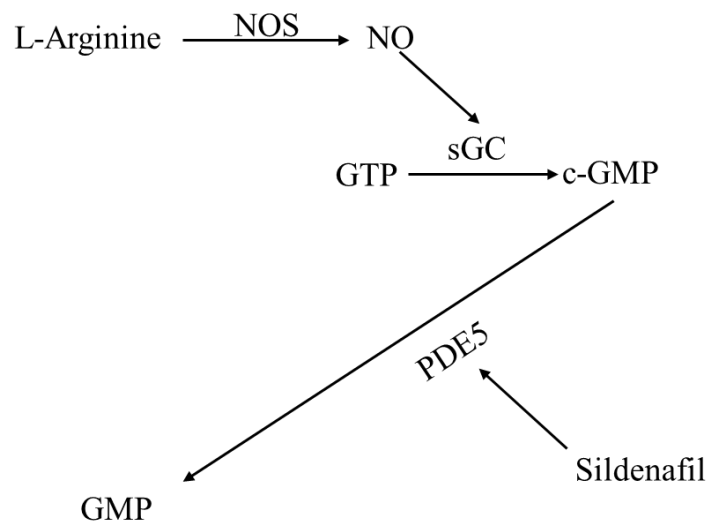

Figure 2. the flow chart from [29] shows NO/cGMP signal pathway.

4.4. Conventional Chinese herbal medicine

Huangqi sijnzi decoction may play a beneficial role in treating AD. The two most important components in Huangqi sijnzi decoction are Quercetin and Formononetin. The strongest inhibitor of acetylcholinesterase is Formononetin. In vitro experiments show that Formononetin has a neuroprotective effect and can protect brain cells from oxidative damage [30].

Table1. The potential drug for the treatment of AD.

Name	Characteristic	Effects/mechanism in AD
Muti-sensory gamma stimulation	Physical therapy	Improves patients' sleep and cognition;
Deep brain stimulation (DBS)		Decreases loss of brain volume
Hyperbaric oxygen therapy		Improve memory; Reduce A β plaque load Reduce intracranial pressure Improving oxygen deprivation to the brain
Mesenchymal stem cell therapy	Non-drug therapy	Reduces brain inflammation; Improves the function of blood vessels.
Gene therapy		Modifies some important genes that are risk of AD.
GLP-1	Glucagon-like peptide-1	Improves cognitive function and oxidative stress; PI3K/Akt pathway Increase cGMP level by NO/cGMP pathway;
Sildenafil	Phosphodiesterase-5 inhibitors	increase neurite outgrowth; reduce aberrant phosphorylation of Tau protein.
UMI-77	Releases MCL-1	Selectively degrade damaged mitochondria.
GV-971	Oral oligosaccharide, targeting at gut microbial	Suits mild or moderate AD improve cognitive function by regulating gut-microbiota-brain axis.
Donanemab Lecanemab (BAN2401) Aducanumab Varoglutamstat	An A β antibody targeting A β plaque	Clear the deposition of A β
PBD-C06	Targeting pGluA β 42 A humanized, deimmunized IgG1 antibody, targeting pGluA β 42	Inhibiting pGluA β 42
PROTAC	Targeting at Tau degradation	Clears Tau aggregation efficiently improves cognition and synaptic functions.
AADvac1	An active peptide vaccine targeting at Tau protein	Reduces NFL; reduces tau and phosphor-tau in CSF
levetiracetam	Antiepileptic drug	Improves spatial memory and executive function
Axitinib	Anti-cancer drug	Restores the integrity of blood-brain barrier; reduces A β deposition

Table1. (continued).

Sildenafil	Phosphodiesterase-5 inhibitors			Increase cGMP level by NO/cGMP pathway; increase neurite outgrowth; reduce aberrant phosphorylation of Tau protein.
Huangqi decoction	sijunzi	Conventional medicine	Chinese herbal	Inhibits acetylcholinesterase; alleviates oxidative damage of nerve cells.

5. Conclusion

Alzheimer's disease is the most common cause of dementia. According to the most recent estimates, the global incidence of dementia will quadruple by 2050. Some hypotheses are put forward that A β plaque maybe a consequence of AD pathology, other than a triggering factor. According to the current studies on the pathogenesis of AD, the pathways are very complicated. Some mechanisms are still being investigated or discovered, such as loss of mitochondrial dynamics, microglia-influencing hypothesis which opens up new avenues for therapeutic development. In addition, more developing drugs targets the supportive mechanisms of neurons like increasing energy metabolism in pathological conditions. Treatment for AD can only be symptomatic that can't cure patients fundamentally until the pathogenesis of the disease is fully understood. In the future, there are some ways to treat AD: 1. Some deep study needed to learn the etiology and pathogenesis of the disease, new drugs should focus on specific molecular sites; 2. developing gene therapy to repair damaged nervous cells; 3. stem cells therapy has broad prospects in treating neurodegenerative diseases; 4. some drugs targeting at regulating gut microbial have a protective effect on AD.
